[57] **ABSTRACT**

A computer processing system containing a plurality of identical processor elements each of which does not retain execution state information from prior operations. The plurality of identical processor elements operate on a statically compiled program which, based upon detected natural concurrencies in the basic blocks of the programs, provide logical processor numbers and an instruction firing time to each instruction in each basic block. Each processor element is capable of executing instructions on a per instruction basis such that dependent instructions can execute on the same or different processor elements. A given processor element is capable of executing an instruction from one context followed by an instruction from another context through use of shared storage resources.

1

PARALLEL PROCESSOR SYSTEM FOR PROCESSING NATURAL CONCURRENCIES AND METHOD THEREFOR

This is a division of application Ser. No. 794,221, filed Oct. 31, 1985, now U.S. Pat. No 4,847,755, issued July 11, 1989.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention generally relates to parallel processor computer systems and, more particularly, to parallel processor computer systems having software for detecting natural concurrencies in instruction streams and having a plurality of identical processor elements for processing the detected natural concurrencies.

2. Description of the Prior Art

Almost all prior art computer systems are of "Von Neumann" construction. In fact, the first four generations of computers are Von Neumann machines which use a single large processor to sequentially process data. In recent years, considerable effort has been directed towards the creation of a fifth generation computer which is not of the Von Neumann type. One characteristic of the so-called fifth generation computer relates to its ability to perform parallel computation through use of a number of processor elements. With the advent of very large scale integration (VLSI) technology, the economic cost of using a number of individual processor elements becomes cost effective.

An excellent survey of multi-processing technology involving the use of parallel architectures is set forth in the June, 1985 issue of COMPUTER, published by the IEEE Computer Society, 345 East 47th Street, New York, New York 10017, which is not believed to be prior art to the present invention but serves to define the activity in this field. In particular, this issue contains the following articles:

(a) "Essential Issues in Multi-processor Systems" by Gajski et al.;

(b) "Microprocessors: Architecture and Applications" by Patton; and

(c) "Research on Parallel Machine Architecture for Fifth-Generation Computer Systems" by Murakami et al.

In addition, an article in the IEEE Spectrum, November, 1983, entitled "Computer Architecture" by A. L. Davis discusses the features of such fifth-generation machines. Whether or not an actual fifth generation machine has yet been constructed is subject to debate, but various features have been defined and classified.

As Davis recognizes, fifth-generation machines should be capable of using multiple-instruction, multiple-data (MIMD) streams rather than simply being a single instruction, multiple-data (SIMD) system. The present invention is believed to be of the fifth-generation non-Von Neumann type which is capable of using MIMD streams in single context (SC-MIMD) or in multiple context (MC-MIMD). The present invention, however, also finds application in the entire computer classification of single and multiple context SIMD (SC-SIMD and MC-SIMD) machines as well as single and multiple context single-instruction, single data (SC- o SISD and MC-SISD) machines.

While the design of fifth-generation computer systems is fully in a state of flux, certain categories of systems have been defined. Davis and Gajski, for example, base the type of computer upon the manner in which

2

"control" or "synchronization" of the system is performed. The control classification includes control-driven, data-driven, and reduction (or demand) driven. The control-driven system utilizes a centralized control such as a program counter or a master processor to control processing by the slave processors. An example of a control-driven machine is the Non-Von-1 machine at Columbia University. In data-driven systems, control of the system results from the actual arrival of data required for processing. An example of a data-driven machine is the University of Manchester dataflow machine developed in England by Ian Watson. Reduction driven systems control processing when the processed activity demands results to occur. An example of a reduction processor is the MAGO reduction machine being developed at the University of North Carolina, Chapel Hill. The characteristics of the non-Von-1 machine, the Manchester machine, and the MAGO reduction machine are carefully discussed in the Davis article. In comparison, data-driven and demand-driven systems are decentralized approaches whereas control-driven systems are centralized. The present invention is more properly categorized in a fourth classification which could be termed "time-driven." Like data-driven and demand-driven systems, the control system of the present invention is decentralized. However, like the control-driven system, the present invention conducts processing when an activity is ready for execution.

It has been recognized by the Patton, Id. at 39, that most computer systems involving parallel processing concepts have proliferated from a large number of different types of computer architectures. In such cases, the unique nature of the computer architecture mandates or requires either its own processing language or substantial modification of an existing language to be adapted for use. To take advantage of the highly parallel structure of such computer architectures, the programmer is required to have an intimate knowledge of the computer architecture in order to write the necessary software. As a result, porting programs to these machines requires substantial amounts of the users effort, money and time.

Concurrent to this activity, work has also been progressing on the creation of new software and languages, independent of a specific computer architecture, that will expose (in a more direct manner), the inherent parallelism. Hence, most effort in designing supercomputers has been concentrated at the hardware end of the spectrum with some effort at the software end.

Davis has speculated that the best approach to the design of a fifth-generation machine is to concentrate efforts on the mapping of the concurrent program tasks in the software onto the physical hardware resources of the computer architecture. Davis terms this approach one of "task-allocation" and tauts it as being the ultimate key to successful fifth-generation architectures. He categorizes the allocation strategies into two generic types. "Static allocations" are performed once, prior to execution, whereas "dynamic allocations" are performed by hardware whenever the program is executed or run. The present invention utilizes a static allocation strategy and provides task allocations for a given program after compilation and prior to execution. The recognition of the "task allocation" approach in the design of fifth generation machines was used by Davis in the design of his "Data-driven Machine-II" constructed at the University of Utah. In the Data-driven Machine-II, the program was compiled into a program

5,021,945

3

graph that resembles the actual machine graph or architecture

Task allocation is also referred to as "scheduling" in the Gajski article. Gajski sets forth levels of scheduling to include high level, intermediate level, and low level scheduling. The present invention is one of low-level scheduling, but it does not use conventional scheduling policies of "first-in-first-out", "round-robin", "shortest type in job-first", or "shortest-remaining-time " Gajski also recognizes the advantage of static scheduling in that overhead costs are paid at compile time. However, Gajski's recognized disadvantage, with respect to static scheduling, of possible inefficiencies in guessing the run time profile of each task is not found in the present invention. Therefore, the conventional approaches to low-level static scheduling found in the Occam language and the Bulldog compiler are not found in the software portion of the present invention. Indeed, the low-level static scheduling of the present invention provides the same type, if not better, utilization of the processors commonly seen in dynamic scheduling by the machine at run time. Furthermore, the low-level static scheduling of the present invention is performed automatically without intervention of programmers as required (for example) in the Occam language.

Davis further recognizes that communication is a critical feature in concurrent processing in that the actual physical topology of the system significantly influences the overall performance of the system.

For example, the fundamental problem found in most data-flow machines is the large amount of communication overhead in moving data between the processors. When data is moved over a bus, significant overhead, and possible degradation of the system, can result if data must contend for access to the bus. For example, the Arvind data-flow machine, referenced in Davis, utilizes an I-structure stream in order to allow the data to remain in one place which then becomes accessible by all processors. The present invention teaches a method of hardware and software based upon totally coupling the hardware resources thereby significantly simplifying the communication problems inherent in systems that perform multiprocessing.

Another feature of non-Von Neumann type multiprocessor systems is the level of granularity of the parallelism being processed. Gajski terms this "partitioning." The goal in designing a system according to Gajski is to obtain as much parallelism as possible with the lowest amount of overhead. The present invention performs concurrent processing at the lowest level available, the "per instruction" level. The present invention teaches a method whereby this level of parallelism is obtainable without execution time overhead.

Despite all of the work that has been done with multiprocessor parallel machines, Davis (Id. at 99) recognizes that such software and/or hardware approaches are primarily designed for individual tasks and are not universally suitable for all types of tasks or programs as has been the hallmark with Von Neumann architectures. The present invention sets forth a computer system that is generally suitable for many different types of tasks since it operates on the natural concurrencies existent in the instruction stream at a very fine level of granularity.

The patent invention, therefore, pertains to a non-Von Neuman MIMD computer system capable of operating upon many different and conventional programs by a number of different users. The natural concurren-

4

cies in each program are statically allocated, at a very fine level of granularity, and intelligence is added to each instruction at essentially the object code level. The added intelligence includes a logical processor number and an instruction firing time in order to provide the time-driven decentralized control for the present invention. The detection and low level scheduling of the natural concurrencies and the adding of the intelligence occurs only once for a given program, after conventional compiling of the program, without user intervention and prior to execution. The results of this static allocation are executed on a system containing a plurality of identical processor elements. These processor elements are characterized by the fact that they contain no execution state information from the execution of previous instructions, i.e., they are context free. In addition, a plurality of contexts, one for each user, are provided wherein the plurality of context free processor elements can access any storage resource contained in any context through total coupling of the processor element to the shared resource during the processing of an instruction. Under the teachings of the present invention no condition code or results registers are found on the individual processor elements.

Based upon the features of the present invention, a patentability investigation was conducted resulting in the following references:

In the two McDowell references, a parallel processing system utilizing low level parallelism was disclosed. McDowell differentiates between low level and high level parallelism in that low level parallelism pertains to the execution of two or more machine level operations in parallel whereas high level parallelism is the parallel execution of high level language constructs which includes source language statements, tasks, procedures, or entire programs.

Like the present invention, McDowell identifies and statically schedules low level parallel operations found in existing "sequential" programming languages. Further, he does not require the creation of special purpose programming languages or user modifications to the parallelism existing with the program at compile time, rather he simply analyzes the low level parallelism existing within the basic blocks (BBs) that make up the program.

In the McDowell SIMAC system, processor elements are identical and communicate through a shared memory and a set of shared registers. The processor elements are controlled by a control processor that is fed by a single instruction stream.

McDowell recognizes his particular parallel processing system does not fit into the standard categories of: homogeneous multiprocessors, non-homogeneous multi-processors, array processors, and pipeline processors. Rather, McDowell classified his computer system in the class of Schedulable Parallel Instruction Execution

6

(SPIE) computers McDowell's reasoning as to why SIMAC is categorized as a SPIE processor is as follows:

SPIE processors have only one instruction stream and are therefore immediately eliminated from the first two groups. They have some of the characteristics of array processors, but they are distinctly different in that each of the several processing elements may be executing different operations. In array processors all processing elements are restricted to executing the same instruction on different data. SPIE processors are also similar in capability to pipelined machines but again they are distinct in that each processing element may be given a new operation each instruction cycle that is independent of the operation it was performing in the previous cycle. Pipelined machines only specify a single operation per instruction cycle, and then other operations on other processing elements may be triggered from that one initial operation. Dissertation Thesis at 11.

The present invention also is properly categorized as a SPIE processing system since each processor element may be given a new operation each instruction cycle that is independent of the operation it was performing in the previous cycle. Hence, the McDowell reference provides important background material to the teachings of the present invention. However, important distinctions exist between McDowell's SIMAC system and the system of the present invention. SIMAC is quoted as being a SPIE machine that can perform scalar concurrent execution of a single user's program (i.e., SIMD). The present invention also fits into this SIMD category, however, it is further capable of performing scalar concurrent execution for multiple instruction streams (i.e., MIMD) and further for single or multiple context (i.e., SC-MIMD or MC-MIMD).

SIMAC implicitly assigns instructions (termed "machine operations") to processor elements by virtue of the physical ordering of the instructions when they are grouped together into "parallel instructions." The identity of the assigned processor is not a part of the instruction per se. The present invention teaches that the order of the instructions within a group of concurrently executable instructions does not determine the processor assignment. Rather, the processor assignment, under the teachings of the present invention, is explicitly made by adding a logical processor number to become physically part of the instruction which is performed in software prior to execution. In addition, the present invention distinguishes the logical processor number from the actual physical processor number that executes the instruction. This allows for further machine independence of the software in that the physical processor assignment is performed dynamically at execution time.

SIMAC code generation can be divided into three components during which the static allocation and scheduling of its instructions are performed (prior to execution). First, is the determination of the machine operations to be performed. This is the typical code generation phase of a compiler. Second, is the formation of these operations into parallel instructions containing the operations that can be done in parallel. The third component comprises the ordering (scheduling) of the parallel instructions so

"...to allow the execution of two [parallel instructions] containing different length [machine opera-

5,021,945

7

tions] to overlap using only simple hardware controls.." McDowell's Conference Paper @ Pg. 475. In other words, McDowell attempts to schedule instructions with differing length execution times so that they can execute concurrently with a minimum amount of hardware support. To the contrary, the present invention does not require this third component. The use of the logical processor number and the instruction firing time that are physically attached to each instruction preclude the need for this phase.

As stated above, SIMAC performs its concurrency detection during compile time only. As a result, the static analysis of the concurrency present within the instruction stream is language dependent. In contrast, the concurrency detection of present invention is language independent since the detection takes place after compilation and prior to execution. The present invention can perform its concurrency detection and scheduling without requiring any modifications to the compiler.

Like SIMAC, the present invention is designed to be independent of the number of processor elements contained within the system. The processor elements in SIMAC, however, are conventional load/store RISC style processors that contain contextual information regarding the state of the previous execution status. These are the "T" and "V" bits associated with each of the SIMAC processor elements. These are used for branching and are the result of executing certain comparison and test instructions. The processor elements of the present invention are context free processors that support a RISC-like instruction set. The term "context free" means that the processor elements contain no state information, e.g., condition codes, registers, program status words, flags, etc. Like SIMAC, the processor elements of the present invention contain no local registers. All operations are performed on data already stored in an array of registers and are accessible by any of the individual processor elements through a register switch.

In SIMAC, only a single set (or level) of 32 registers is available and is shared by all processor elements. Each register may be physically read by any or all processor elements simultaneously. However, only one processor element may write into a specific register at any one time. (Dissertation Thesis at 26) Whereas the registers of this invention also have this characteristic, the architecture of the register set in the present invention is much different than that of the SIMAC machine. The SIMAC machine contains a single level of registers. The present invention contains a number of levels of register sets; each level corresponding to a procedural depth relative to the main program. In addition, each set of levels is replicated to support each context or user that is currently being executed. Thus, under the teachings of the present invention, contexts may be switched or procedures entered without having to flush any registers to memory.

SIMAC does not discuss the need for the production and assignment of condition codes. Without the use of multiple condition code sets, it is not possible to distribute instructions which affect the condition codes across multiple processor elements and guarantee proper condition code data for the execution of subsequent dependent instructions. The present invention teaches a method for the management and assignment of multiple condition code sets. The management and assignment of

8

this resource is analogous to that done for the register resources.

SIMAC also requires a separate control processor that performs the branching operations. This processor contains the program counter and executes the branch operations Each processor element in SIMAC contains three status bits used in the branching operations. The present invention does not use a control processor, nor does it use a program counter and its processor elements contain no such status bits SIMAC is a centralized control system under the Davis classification whereas the present invention is decentralized.

Hence, the present invention is significantly more general than the SIMAC approach since the present invention performs inter-program parallelism as well as intra-program parallelism.

In addition, while SIMAC provides a register array, McDowell indicates that this, perhaps is not desirable because of cost and proposes that future work be done on an arrangement other than shared registers (Id. at 79) The present invention not only makes use of the shared register concept but also provides sharing of condition codes and the management of those condition codes as well. While McDowell, implicitly, assigns the machine operations to his processor elements, the present invention explicitly extends each instruction with a logical processor number as well as providing a specific firing time for the instruction. There is no disclosure in SIMAC of either a firing time or a logical processor number. Therefore, the master controller, in SIMAC, uses a program counter that provides the control for the processor elements. Under the teaching of the present invention, a set of logical resource drivers (one for each context or user) is provided and instruction selection is based upon the firing times added to each instruction within a basic block (i.e., time driven).

DeSantis sets forth in U.S. Letters Pat. Nos. 4,466,061 and 4,468,736 a concurrent data processor which is:
    adapted to receive strings of object code, form them
        into higher level tasks and to determine sequences
        of such tasks which are logically independent so
        that they may be separately executed ('736 patent
        at col 2, lines 50–54).
The logically independent sequences are separately executed by a plurality of processor elements. The first step in the DeSantis approach is to hardware compile the program into strings of object code or machine language in a form which is particularly designed for the computer architecture to provide a dependency free code. The DeSantis invention then forms an independency queue so that all processing for the entire queue is accomplished in one step or cycle. The hardware structure for the DeSantis approach is set forth in FIG. 2 of the patent and contemplates the use of a number of small processor elements (SPEs) each with local memories.

The nature of the interconnection between the local memories of each SPE and the direct storage module 14 is not clear. The patent states:
    In the meantime, respective data items required for
        execution have been fetched from main memory
        and stored at the appropriate locations in local
        memories which locations are accessed by the
        pointers and the job queue ('736 patent at Col. 6,
        Lines 19–23).
It does not appear from this description, that each individual SPE has access to the local memories of the other SPE rather, this allocation seems to be made by

5,021,945

9   10

the direct storage module (DSM). Hence, under DeSantis, the queue which contains the independent sequences for processing delivers the string to an identified processor element, so that the processor elements can process all strings concurrently and in parallel, the direct storage module must deliver the necessary results into the local memories for each SPE. With respect to each individual SPE, DeSantis states:

> Since the respective processors are provided to execute different functions, they can also be special purpose microprocessors containing only that amount of logic circuitry required to perform the respective functions. The respective circuits are the arithmetic logic unit, shift unit, multiply unit, indexing unit, string processor and decode unit ('736 patent at Col. 7, Lines 7–13).

The primary difference between the approach of the present invention and DeSantis relates to when the detection of the concurrency occurs. TDA performs its concurrency detection during a pre-processing stage at the object level using information normally thrown away by the source code level language processors. DeSantis performs it with part of the hardware collectively called the cache mechanism 10 (see FIG. 1) dynamically during execution time. Hence, the DeSantis approach constantly uses overhead and resources to hardware de-compile each program. A secondary difference relates to the execution of individual streams of dependent instructions. DeSantis requires that a stream of dependent instructions be executed on the same processor. To the contrary, the present invention permits the execution of a stream of dependent instructions on the same or multiple processor elements.

It is believed that the aforesaid McDowell and DeSantis references are the most pertinent of the references discovered in the patentability investigation and, therefore, more discussion occurs for it than the following references.

J.R. Vanaken in "The Expression Processor" article classifies his processor as a "direct descendant of the tree processor." There is a similarity between the Vanaken architecture and the architecture of the present invention wherein each processor element is capable of accessing, through an alignment network, any one of a number of registers located in a register array. Vanaken utilizes thirty-two processor elements and eight register modules in the register storage. A crossbar switch is disclosed for the alignment network. In this configuration, the identical processor elements of Vanaken do not exchange data directly with the main memory. Rather, data transfers take place between the register storage and the memory. This is not the configuration of the present invention. Vanaken further contemplates utilizing a separate compiler (only for scaler programs) for the detection of low level parallelism and for the assignment of detected parallelism to individual processor elements. How this is done, however, is not disclosed. Vanaken simply discloses the desired goals:

> First, it [the compiler] must detect the potential parallelism in the program. Second, it must map detected parallelism onto the structure of the target machine. *The Expression Processor* at 535.

Vanaken refers only to the parallelism detection techniques presented by Kuck. However, Vanaken's tree structured processor element architecture requires that the computational task be modeled as a computational tree, or as a computational wavefront (wavefront ref: Kuck's work). In the former case, processor assignment

is accomplished by assigning a processor to each node in the tree. If there are more nodes in the tree than processors, the task must be broken down into smaller subtasks that will fit on the processor array. In the latter case, the wavefront propagates from the lowest level of processors to the next higher level and so on until the highest level is achieved. Again, if the number of processors required by the wavefront is greater than the number of processors available, the task must be broken into smaller subtasks. This type of flow through ordered processors does not exist in the present invention.

In the Hagiwara articles, the disclosed MIMD QA-1 computer system appears to be a very long instruction word (VLIW) machine having a 160 bit or 80 bit word. The Hagiwara references term this a "horizontal-type microinstruction" and the QA-1 machine takes advantage of the low-level parallel concurrency, at the microcode level. The QA-2 system has 62 working registers constructed of large capacity/high-speed RAM chips interconnected over a network to each of the four processor elements. The earlier QA-1 system utilized a stack of only 15 working registers. Hence, the QA-2 hardware design contemplates the use of individual processor elements having full access to a number of working registers through a switching network. In QA-2, through use of the network, the results of one processor element are delivered to a working register which is then delivered to another processor element as input data. Hence, the QA-1 and QA-2 configurations take advantage of scaler concurrency, multiple ALUs, and the sharing of working registers. The QA-2 approach modifies the QA-1 approach by providing special purpose registers in the register file (i.e., constant, general, indirect, and special); such a division, however, is not apparent in the QA-1 architecture. From a compiling point of view, the QA-1 was primarily designed to be encoded by a programmer at the microcode level to take programming advantage of the inherent power of the system's architecture. The QA-2 machine which is directed towards the personal computer or local host computer (e.g., for laboratory use) contemplates that programs written in high-level languages will be compiled into the QA-2 microprogrammed interpretations.

The four Fisher references disclose a SIMD system based upon a "very long instruction word" (VLIW). The goal presented in these articles is to determine the low level parallelism or "fine-grained parallelism" of a program in a separate compiler so that all individual movements of the data within the VLIW machine are completely specified at compile time. At the outset, it is important to recognize that the hardware architecture for implementing Fisher's VLIW machine is not discussed in these references other than in a general sense. Fisher contemplates:

> Each of the eight processors contain several functional units, all capable of initiating an operation in each cycle. Our best guess is two integer ALUs, one pipelined floating ALU, one memory port, several register banks, and a limited crossbar for all of these to talk to each other. *Computer* article at pg. 50.

Rather, the Fisher articles concentrate on the software compiling technique called "trace scheduling" and nicknamed BULLDOG. Fisher further requires an instruction word of "fixed length." The length of Fisher's instruction word, therefore, amount of hardware required to process the instruction word. In that respect, the present invention is much more dynamic and fluid

5,021,945

11

since it can have any number of processors wherein each processor processes the parallel instruction during the instruction firing time.

Lorie et al. (U S. Letters Pat. No. 4,435,758) sets forth a technique for ordering instructions for parallel execu- 5 tion during compile time by adding code to the instruction stream The present invention does not add code to the instruction stream.

The Reigel patent (U S. Letters Pat. No. 3,611,306) relates to the ordering of the detected parallel instruc- 10 tions for a particular computer architectural approach.

The patent issued to Freiman, et al. (U.S. Letters Pat. No. 3,343,135) teaches a dynamic compiling system, hardware based, for use in a multiprocessor environment for analyzing particular types of mathematical 15 expressions for parallel execution opportunities and then to automatically assign individual operations to processors within the system. Freiman first identifies the concurrencies, in the hardware, and determines the time periods within which the operations may be per- 20 formed. These determined times are "the earliest times in which a given operation may be performed." The Freiman invention also analyzes the particular mathematical expression and determines, in the hardware, "the latest times in which an operation can be per- 25 formed." This information generated from the analysis of the mathematical algorithm is stored in a word register which is then used in the multiprocessor environment. Each processor has associated with it a processor control which for all processors is identical and which 30 is driven by six control fields. One function of the control block is to determine whether or not a particular processor is ready to receive a job, to indicate when it has received a job, and to analyze each job to see if the processor can proceed immediately with the job or 35 whether it must wait until one of the operants of the job is already assigned. Once a processor is assigned to a task the necessary data contained in the results register may not be available at that particular time and hence the processor must wait until a test of the results register 40 indicates that the result is available. Once the result is available, the processor will perform its operation and place its result in the appropriate result register for access by another processor. All processors in Freiman have access to the results register by means of a crossbar 45 switch.

The patent issued to Dennis et al. (U S. Letters Pat. No. 4,153,932) teaches a highly parallel multiprocessor for the concurrent processing of programs represented in data flow form. Specifically, a mathematical compu- 50 tation as shown at column 5, lines 17–23 and as represented in FIG. 2 in data flow language is used as an example Hence, the data flow form is generated and stored in the memory of the processor in designated instruction cells wherein each instruction cell corre- 55 sponds to an operator in the data flow program. In operation, when an instruction cell is complete (i.e., containing the instruction and all necessary operands), a signal is generated to the Arbitration Network which directs the flow of the information in the instruction cell 60 to the identified processor. The processor operates on the information and delivers it back through a distribution network into the main memory.

The patent issued to Culler (U.S Letters Pat. No. 3,771,141) discloses a high speed processor capable of 65 parallel operations on data. Multiple or parallel processors, however, are not used. Rather, the parallelism is achieved structurally by implementing each of the pro-

12

cessor's data registers with four separate multi-bit data input ports. Hence, four operations can be performed at once. This results in a "tightly coupled" arrangement since the data from any given processor register is ready to be received by any other register at the next clock cycle. The control of which register is to receive which information occurs at the object code level and, as shown in Table 1 of Culler, four additional fields are provided in each object code instruction for controlling the flow of data among the processor's registers Culler states:

> The data pad memory is tightly coupled to the arithmetic unit and serves as an effective buffer between the high speed arithmetic unit and a large capacity random access core memory. As an indication of the effective speed, a complete multiplication of two signed eight bit words can be accomplished in three cycles or 375 nanoseconds.

The Gilliland et al. patent (U.S. Letters Pat. No. 4,229,790) sets forth a processor for processing different and independent jobs concurrently through the use of pipelining with precedent constraints. The Gilliland invention is capable of processing programming tasks concurrently as well as processing the parallel parts of each programming task concurrently. It appears that the invention operates on concurrencies in the program at the source code level rather than at the object code level. The Gilliland processor is capable of processing up to 128 parallel processor paths.

The patent issued to Blum et al (U.S. Letters Pat. No. 4,109,311) relates to a data processing system based upon time slice multiprogramming. The Blum invention contemplates a conventional multiprocessor arrangement wherein a first processor controls a keyboard and display interface, a second processor controls printer, disk storage, and tape storage interface, and a third processor executes the problem oriented programs located in the main storage.

Gruner (U.S. Letters Pat. No. 4,104,720) sets forth a CPU control multiprocessor system wherein each parallel processor is directly interfaced through an interface control circuit to the CPU. Each interface circuit contains memory for storing portions of the micro instructions contained within the CPU. Gruner calls this an "extension" of the micro instructions from the CPU into the interface circuit for each parallel processor. The Gruner system while controlling each interface circuit to allocate and to assign concurrent tasks utilizes a conventional bus structure for the transfer of information between the processors.

The patent issued to Caril (U.S. Letters Pat. No. 4,241,398) relates to a supervisory control system wherein a central processing unit controls and supervises the operation of a number of remote processing units. The Caril invention relates to a low overhead line protocol for controlling the asynchronous exchange of communication information between the central processing unit and each remote processing unit.

Bernhard et al. (U.S. Letters Pat No. 4,228,495) relates to a multiprocessor numerical control system. The Bernhard invention relates to a main processor coupled over a bus structure to a plurality of programmable interface processors.

Koehler et al. patent (U.S. Letters Pat. No. 4,270,167) discloses a multiprocessor arrangement wherein a central processor has primary control and access to a local bus and wherein the remaining plurality of processors also share access to the local bus. Arbitration among the

5,021,945

13

processors is provided to the local bus as well as the generation of query status and processor status signals.

The patent issued to Kober (U.S. Letters Pat. No. 4,181,936) relates to a distributed computing system for increasing the efficiency of the data bus.

The Requa article discusses a piecewise data flow architecture which seeks to combine the strengths of other supercomputers. The goal of the Requa architecture is to take the source code program and recompile it into "basic blocks." These basic blocks are designed to be no longer than 255 instructions and the natural concurrencies existing in each basic block are identified and processed separately by a number of "scaler processors." The natural concurrencies are encoded as part of the instructions to the scaler processors. The concurrent instructions waiting for execution reside in a stack of registers to which all of the scaler processors has access to deliver data into and to receive data from. As in the Dennis approach, when a particular instruction residing in the register is completed (i.e., when a prior data dependency has been satisfied and stored) the scaler instruction apparently raises a flag which will be detected for delivery to a scaler processor.

In the Bernhard article, the author surveys the current state of art concerning supercomputer design. The article discusses the current supercomputer research projects and provides critical comments concerning each type of design. The disclosure in this article appears to be cumulative to the analysis set forth above and none of the approaches set forth suggest the TDA processor register communication technique.

SUMMARY OF INVENTION

The present invention provides a method and a system that is non-Von Neuman and one which is adaptable for use in single or multiple context SISD, SIMD, and MIMD configurations. The method and system is further operative upon a myriad of conventional programs without user intervention.

The present invention statically determines at a very fine level of granularity, the natural concurrencies in the basic blocks (BBs) of programs at essentially the object code level and adds a logical processor number (LPN) and an instruction firing time (IFT) to each instruction in each basic block in order to provide a time driven decentralized control. The detection and low level scheduling of the natural concurrencies and the adding of the intelligence occurs only once for a given program after conventional compiling and prior to execution. At this time all instruction resources are assigned.

The present invention further executes the basic blocks containing the added intelligence on a system containing a plurality of identical processor elements each of which does not retain execution state information from prior operations. Hence, all processor elements are context free. Instructions are selected for execution based on instruction firing time. Each processor element is capable of executing instructions on a perinstruction basis such that dependent instructions can execute on the same or different processor elements. A given processor element in the present invention is capable of executing an instruction from one context followed by an instruction from another context. All context information necessary for processing a given instruction is contained elsewhere in the system.

The system and method of the present invention are described in the following drawing and specification.

14

DESCRIPTION OF THE DRAWING

FIG. 1 is the generalized flow of the TOLL software of the present invention;

FIG. 2 is a graphic representation of a sequential series of basic blocks found within the conventional compiler output;

FIG. 3 is a graphical presentation of the extended intelligence added to each basic block under the teachings of the present invention;

FIG. 4 is a graphical representation showing the details of the extended intelligence added to each instruction within a given basic block;

FIG. 5 is the breakdown of the basic blocks carrying the extended information into discrete execution sets;

FIG. 6 is a block diagram presentation of the architectural structure of the present invention;

FIG. 7a-7c represents an illustration of the network interconnections during three successive instruction firing times;

FIGS. 8-11 are the flow diagrams setting forth the program features of the software of the present invention;

FIG. 12 is the flow diagram for determining the execution sets in the TOLL Software;

FIG. 13 sets forth the register file organization of the present invention;

FIG. 14 illustrates the transfers between registers in levels during a subroutine call;

FIG. 15 sets forth the structure of the logical resource drivers (LRDs) of the present invention;

FIG. 16 sets forth the structure of the instruction caches control and of the caches of the present invention;

FIG. 17 sets forth the structure of the PIQ buffer unit and the PIQ bus interface unit of the present invention;

FIG. 18 sets forth interconnection of the processor elements through the PE-LRD network to the PIQ processor alignment circuit of the present invention;

FIG. 19 sets forth the structure of the branch execution unit of the present invention;

FIG. 20 illustrates the organization of the contexts of the present invention;

FIG. 21 sets forth the structure of one embodiment of the processor element of the present invention; and

FIGS. 22(a) through 22(d) sets forth the data structures in the processor element of FIG. 21.

GENERAL DESCRIPTION

1. Introduction

In the following two sections, a general description of the software and hardware of the present invention takes place The system of the present invention is designed based upon a unique relationship between the hardware and software components. While many prior art approaches have primarily provided for multiprocessor parallel processing based upon a new architecture design or upon unique software algorithms, the present invention is based upon a unique hardware/software relationship. The software of the present invention provides the intelligent information for the routing and synchronization of the instruction streams through the hardware. In the performance of these tasks, the software spatially and temporally manages all user accessible resources, e.g., registers, condition codes, memory and stack pointers. This routing and synchronization is done without any user intervention, and does not require changes to the source code. Additionally, the

5,021,945

15

analysis of an instruction stream to provide the addi-
tional intelligent information for routing and synchroni-
zation is performed only once during the program prep-
aration process (i.e., static allocation) on a given piece
of software, and is not performed during execution (i e,
dynamic allocation) as is found in some conventional
prior art approaches. The analysis is performed on the
object code output from conventional compilers and
therefore is programming language independent.

2. General Software Description

In FIG 1, the general description of the software of
the present invention is set forth and is generally termed
"TOLL." The software TOLL located in a processing
system 160 operates on standard compiler output 100
which is typically object code or an intermediate object
code such as "p-code." It is known that the output of
conventional compilers is a sequential stream of object
code instructions hereinafter referred to as the instruc-
tion stream. Conventional language processors typi-
cally perform the following functions in generating the
sequential instruction stream:

1. lexical scan of the input text,
2. syntactical scan of the condensed input text includ-
ing symbol table construction,
3. performance of machine independent optimization
including parallelism detection and vectorization,
and
4. an intermediate (PSEUDO) code generation in-
cluding instruction functionality, resources re-
quired, and structural properties.

In the creation of the sequential instruction stream, the
conventional compiler creates a series of basic blocks
(BBs) which are single entry single exit (SESE) groups
of contiguous instructions. See, for example, *Principles
of Compiler Design*, Alfred v. Aho and Jeffery D. Ull-
man, Addison Wesley, 1979, pg. 6, 409, 412–413 and
Compiler Construction for Digital Computers, David
Gries, Wiley, 1971. The conventional compiler, al-
though it utilizes basic block information in the perfor-
mance of its tasks, provides an output stream of sequen-
tial instructions without any basic block designations.
The TOLL software of the present invention is de-
signed to operate on the formed basic blocks (BBs)
which are created within a conventional compiler. In
each of the conventional SESE basic blocks there is
exactly one branch (at the end of the block) and there
are no control dependencies; the only relevant depen-
dencies within the block are those between the re-
sources required by the instructions.

The output of the compiler 100 in the basic block
format, is shown in FIG. 2. The TOLL software 110 of
the present invention being processed in a computer 160
performs three basic determining functions on the com-
piler output 100 as shown in FIG. 1. These functions are
to analyze the resource usage of the instructions 120,
extend intelligence for each instruction in each basic
block 130, and to build execution sets composed of one
or more basic blocks 140. The resulting output of these
three basic functions 120, 130, and 140 from processor
160 comprise the TOLL output 150 of the present in-
vention.

At the outset, the TOLL software of the present
invention operates on a compiler output 100 only once
and without user intervention. Therefore, for any given
program, the TOLL software need operate on the com-
piler output 100 only once.

The functions of the TOLL software 110 are to ana-
lyze the instruction stream in each basic block for natu-

16

ral concurrencies, to perform a translation of the in-
struction stream onto the actual hardware system of the
present invention, to alleviate any hardware induced
idiosyncracies that may result from this translation and
to encode the resulting stream into an actual machine
language to be used on the hardware of the present
invention. The TOLL software 110 performs these
features by analyzing the instruction stream and then
assigning context free processor elements and resources
as a result thereof The TOLL software 110 provides
the "synchronization" of the overall system by assign-
ing appropriate firing times to each instruction in the
instruction stream.

Instructions can be dependent on one another in a
variety of ways although there are only three basic
types of dependencies. First, there are procedural de-
pendencies due to the actual structure of the instruction
stream; i.e., instructions may follow one another in
other than a sequential order due to branches, jumps,
etc. Second, operational dependencies are due to the
finite number of hardware elements present in the sys-
tem. These hardware elements include the registers,
condition codes, stack pointers, processor elements, and
memory. Thus if two instructions are to execute in
parallel, they must not require the same hardware ele-
ment unless they are both reading that element (pro-
vided of course, that the element is capable of being
read simultaneously). Finally, there are data dependen-
cies between instructions in the instruction stream. This
form of dependency will be discussed at length later.
However, within a basic block only data and opera-
tional dependencies are present.

The TOLL software 110 maintains the proper execu-
tion of a program; i.e., TOLL must assure that the paral-
lelized code 150 generates the same results as those of
the original serial code. In order to do this, the parallel-
ized code 150 must access the resources in the same
relative sequence as the serial code for instructions that
are dependent on one another; i.e., the relative ordering
must be satisfied. However, independent sets of instruc-
tions may be effectively executed out of sequence.

In Table 1 is set forth an example of a SESE basic
block representing the inner loop of a matrix multiply
routine. This example will be used throughout this spec-
ification and the teachings of the present invention are
application for any routine. The instruction is set forth
in the left hand column and the conventional object
code function for this basic block is represented in the
right hand column.

TABLE 1

INSTRUCTION	OBJECT CODE
LD R0, (R10) +	I0
LD R1, (R11) +	I1
MM R0, R1, R2	I2
ADD R2, R3, R3	I3
DEC R4	I4
BRNZR LOOP	I5

The instruction stream contained within the SESE
basic block set forth in Table 1 performs the following
functions. In instruction I0, register R0 is loaded with
the contents of memory whose address is contained in
R10. The instruction shown above increments the con-
tents of R10 after the address has been fetched from
R10. The same statement can be made for instruction I1,
with the exception that register R1 is loaded and regis-

5,021,945

17

ter R11 incremented. The contents of register R0 are then multiplied with the contents of register R1 and stored in register R2 in instruction I2. In instruction I3, the contents of register R2 and register R3 are added together and stored in register R3. In instruction I4, register R4 is decremented. Note that instructions I2, I3 and I4 also generate a set of condition codes that reflect the status of their respective execution. In instruction I5, the contents of register R4 are indirectly tested for zero (via the condition codes generated by instruction I4). A branch occurs if the decrement operation produced a non-zero value; otherwise execution proceeds with the next basic block's first instruction.

As shown in FIG. 1, the first function performed by TOLL 110 is to analyze the resource usage of the instructions; which in Table 1 are instructions I0 through I5. The TOLL software 110 analyzes each instruction to ascertain the resource requirements of each instruction.

This analysis is important in determining whether or not sets of resources share any elements and, therefore, whether or not the instructions are independent of one another. Clearly, mutually independent instructions can be executed in parallel and are termed "naturally concurrent." Instructions that are independent can be executed in parallel and do not rely on one another for any information nor do they share any hardware resources in other than a read only manner.

On the other hand, instructions that are dependent on one another can be formed into a set wherein each instruction in the set is dependent on every other instruction in that set, although this dependency may not be direct. The set can be described by the instructions within that set, or conversely, by the resources used by the instructions in that set. Instructions within different sets are completely independent of one another, i.e., there are no resources shared by the sets. Hence, the sets are independent of one another.

In the example of Table 1, there are two independent sets of dependent instructions determined by TOLL:

| Set 1: | CC1: | I0, I1, I2, I3 and |
| Set 2: | CC2: | I4, I5 |

As can be seen, instructions I4 and I5 are independent of instructions I0–I3. In set 2, I5 is directly dependent on I4. In set 1, I2 is directly dependent on I0 and I1. Instruction I3 is directly dependent on I2 and indirectly dependent on I0 and I1.

The TOLL software of the present invention detects these independent sets of dependent instructions and assigns condition codes sets such as CC1 and CC2 to each set. This avoids the operational dependency that would occur if only one set of condition codes were available to the instruction stream.

In other words, the results of the execution of instructions I0 and I1 are needed for the execution of instruction I2. Similarly, the results of the execution of instruction I2 are needed for the execution of instruction I3. Thus, the TOLL software 110 determines if an instruction will perform a read and/ or a write to a resource. This functionality is termed the resource requirement analysis of the instruction stream.

It should be noted that, unlike the teachings of prior art, the present invention teaches that it is not necessary for dependent instructions to execute on the same processor element. The determination of dependencies is

18

needed only to assign condition code sets and to assign instruction firing times, as will be described later. The present invention can execute dependent instructions on different processor elements because of the context free nature of the processor elements and the total coupling of the processor elements to the shared resources, such as register files, as will also be described later.

The results of the analysis stage 120, for the example set forth in Table 1, are set forth in Table 2.

TABLE 2

BB	FUNCTION
I0	Memory Read, Reg. Write, Reg. Read & Write
I1	Memory Read, Reg. Write, Reg. Read & write
I2	Two Reg. Reads, Reg. Write, Set Cond. Code (Set #1)
I3	Two Reg. Reads, Reg. Write, Set Cond. Code (Set #1)
I4	Read Reg., Reg. Write, Set Cond Code (Set #2)
I5	Read Cond. Code (Set #2)

In Table 2, for instructions I0 and I1, a register is read and written followed by a memory read (at a distinct address), followed by a register write. Likewise, condition code writes and register reads and writes occur for instructions I2 through I4. Finally, instruction I5 is a simple read of a condition code storage and a resulting branch or loop.

The second pass 130 through the SESE basic block 100 is to add or extend the intelligence of each instruction within the basic block. This is the assignment of an instruction's execution time relative to the execution times of the other instructions in the stream, the assignment of a logical processor number on which the instruction is to execute and the assignment of any static shared context storage mapping information that may be needed.

In order to assign the instruction's firing time, the temporal usage of each resource required by the instruction must be considered. The temporal usage of each resource is characterized by a "free time" and a "load time." The free time is the last time the resource is used by an instruction. The load time is the last time the resource is modified by an instruction. If an instruction is going to modify a resource, it must execute after the last time the resource is used, in other words, after the free time. If an instruction is going to read the resource, it must perform the read after the last time the resource has been loaded, in other words, after the load time.

The link between the temporal usage of each resource and the actual usage of the resource is as follows. If the instruction is going to write/modify the resource, the last time the resource is read or written by other instructions (i.e., the "free time" for the resource) plus one time interval will be the firing time for this resource. The "plus one time interval" comes from the fact that an instruction is still using the resource during the free time. On the other hand, if the instruction reads a resource, the last time the resource is modified by other instructions (i.e., the load time for the resource) plus one time interval will be the resource firing time. The "plus one time interval" comes from the time required for the instruction that is performing the load to execute.

The above discussion assumes that the exact location of the resource that is accessed is known. This is always true of resources that are directly named such as registers and condition codes. However, memory operations

5,021,945

19

20

may, in general, be to unknown (at compile time) locations. In particular, addresses that are generated by effective addressing constructs fall under this domain. In the previous example, it has been assumed (for the purposes of communicating the basic concepts of TOLL) that the addresses used by instructions I0 and I1 are distinct. If this were not the case, the TOLL software would assure that only those instructions that did not use memory would be allowed to execute in parallel with an instruction that was accessing an unknown location in memory.

The resource firing time is evaluated by TOLL 110 for each resource that the instruction uses. These resource firing times are then compared to determine which is the largest or latest with this maximum value determining the actual firing time assigned to the instruction. At this point, TOLL 110 then updates all resources' free and load times, to reflect this instruction's firing time. TOLL 110 then proceeds by analyzing the next instruction.

There are many methods available for determining interinstruction dependencies within a basic block. The previous discussion is just one possible implementation assuming a specific compiler-TOLL partitioning. Many other compiler-TOLL partitionings and methods for determining inter-instruction dependencies may be possible and realizable to one skilled in the art. As an example, the TOLL software uses a linked list analysis to represent the data dependencies within a basic block. Other possible data structures that could be used are trees, stacks, etc.

Assume a linked list representation is desired for the analysis and representation of the inter-instruction dependencies. Each register is associated with a set of pointers to the instructions that use the value contained in that register. For the matrix multiply example in Table 1, the resource usage is set forth in the following:

TABLE 3

Resource	Loaded By	Read By
R0	I0	I2
R1	I1	I2
R2	I2	I3
R3	I3	I3, I2
R4	I4	I5
R10	I0	I0
R11	I1	I1

Thus, by following the "read by" links and knowing the resource utilization for each instruction, the independencies of Sets 1 and 2, above, are constructed in the analyze instruction stage 120 by TOLL 110.

For purposes of the example of Table 1, it is assumed that the basic block commences with an arbitrary time interval, in an instruction stream, such as time interval, for example purposes only, T16. In other words, this particular basic block in time sequence is assumed to start with time interval T16. The results of the analysis in stage 120 are set forth in Table 4.

TABLE 4

REG	I0	I1	I2	I3	I4	I5
R0	T16		T17			
R1		T16	T17			
R2			T17	T18		
R3				T18		
R4					T16	

TABLE 4-continued

REG	I0	I1	I2	I3	I4	I5
CC1			T17	T18		
CC2						T17
R10	T16					
R11		T16				

The left hand column of Table 4 relates to the identity of the register or condition code storage whereas the rows in the table represent the instructions in the basic block example of Table 1. Instruction I0 requires that a register be read and written and another register written at time T16, the start of the basic block. Hence, at time T16, register R10 is read from and written into and register R0 is written into.

Under the teachings of the present invention, there is no reason that registers R1, R11, and R4 cannot also have operations performed on them during time T16. These three instructions, I0, I1, and I4, are data independent of each other and can be operated on concurrently during time T16. Instruction I2 requires first that registers R0 and R1 be operated on so that they may be multiplied together and the results stored in register R2. Although, register R2 could be operated on in time T16, instruction I2 is data dependent and depends upon the results of loading registers R0 and R1, which occurs during time T16. Therefore, the completion of instruction I2 is data dependent and must occur during or after timeframe T17. Hence, in Table 4 above, the entry T17 for the intersection of instruction I2 and register R2 is underlined because it is data dependent. Likewise, instruction I3 requires data to be present in register R2 which first occurs during time T17. Hence, register R2 can have an operation occur on it only during or after time T18. As it turns out, instruction I5 depends upon the reading of the condition code storage CC2 which is updated in instruction I4. The reading of the condition code storage is data dependent upon the results stored in time T16 and, therefore, must occur during or after the next time, T17.

Hence, in stage 130, the object code instructions are assigned "instruction firing times" (IFTs) as set forth in Table 5 based upon the above analysis.

TABLE 5

OBJECT CODE	INSTRUCTION FIRING TIME (IFT)
I0	T16
I1	T16
I2	T17
I3	T18
I4	I16
I5	T17

Each of the instructions in the sequential instruction stream in a basic block can be performed in the assigned time intervals. As is clear in Table 5, the same six instructions of Table 1 normally processed sequentially in six cycles can be processed, under the teachings of the present invention, in only three firing times: T16, T17, and T18. The instruction firing time (IFT) provides the "time-driven" feature of the present invention.

The next function in the extend intelligence stage 130 is to reorder the natural concurrencies in the instruction stream according to instruction firing times (IFTs) and then to assign the individual logical parallel processors. It should be noted that the reordering is only required

5,021,945

21

due to limitations in currently available technology. If true fully associative memories were available, the reordering of the stream would not be required and the processor numbers could be assigned in a first come, first served manner. The hardware of the instruction selection mechanism could be appropriately modified by one skilled in the art to address this mode of operation.

For example, assuming currently available technology, and a system with four parallel processor elements (PEs) and a branch execution unit (BEU) within each LRD, the processor elements and the branch execution unit can be assigned, under the teachings of the present invention, according to that set forth in Table 6 below. It should be noted that the processor elements execute all non-branch instructions, while the branch execution unit (BEU) of the present invention executes all branch instructions. These will be described in greater detail subsequently.

TABLE 6

Logical Processor Number	T16	T17	T18
0	I0	I2	I3
1	I1	—	
2	I4	—	—
4	—	—	—
BEU	—	I5(delay)	—

Hence, under the teachings of the present invention, during time interval T16, parallel processor elements 0, 1, and 2 concurrently process instructions I0, I1, and I4. Likewise, during the next time interval T17, parallel processor elements 0 and the user's BEU concurrently process instructions I2 and I5. And finally, during time interval T18, processor element 0 processes instruction I3. During instruction firing times T16, T17, and T18, parallel processor element 3 is not utilized in the example of Table 1. In actuality, since the last instruction is a branch instruction, the branch cannot occur until the last processing is finished in time T18 for instruction I3. A delay field is built into the processing of instruction I5 so that even though it is processed in time interval T17, its execution is delayed before looping or branching out until after instruction I3 has executed.

The TOLL software 110 of the present invention in the extend intelligence stage 130 looks at each individual instruction and its resource usage both as to type and as to location (if known) (e.g., Table 3). It then assigns instruction firing times (IFTs) on the basis of this resource usage (e.g., Table 4), reorders the instruction stream based upon these firing times (e.g., Table 5) and assigns logical processor numbers (LPNs) (e.g., Table 6) as a result thereof.

The extended intelligence information involving the logical processor number (LPN) and the instruction firing time (IFT) is added to each instruction of the basic block as shown in FIGS. 3 and 4. As will also be pointed out subsequently, this extended intelligence (EXT) for each instruction in a basic block (BB) will be translated onto the physical processor architecture of the present invention. The physical translation is done by hardware. It is important to note that the actual hardware may contain less, the same as, or more physical processor elements than the number of logical processor elements.

The Shared Context Storage Mapping (SCSM) information shown in FIG. 4 and attached to an instruction has two components, static and dynamic. Static infor-

22

mation is attached by the TOLL software or compiler and is a result of the static analysis of the instruction stream. Dynamic information is attached at execution time by a logical resource drive (LRD) as will be discussed later.

At this stage 130, the TOLL software 110 has analyzed the instruction stream as a set of single entry single exit (SESE) basic blocks (BBs) for natural concurrencies that can be processed individually by separate processor elements (PEs) and has assigned to each instruction an instruction firing time (IFT) and a logical processor number (LPN). Under the teachings of the present invention, the instruction stream is pre-processed by TOLL to statically allocate all processing resources in advance of execution. This is done once for any given program and is applicable to any one of a number of different program languages such as FORTRAN, COBOL, PASCAL, BASIC, etc.

In stage 140, the TOLL software 110 builds execution sets (ESs). These are set forth in FIG. 5 wherein a series of basic blocks (BBs) form a single execution set (ES). Once TOLL identifies an execution set 500, header 510 and/or trailer 520 information is placed on the ends. In the preferred embodiment only header information 510 is attached although the invention is not so limited.

Under the teachings of the present invention, basic blocks generally follow one another in the instruction stream. There may be no need for re-ordering of the basic blocks even though individual instructions within a basic block, as discussed above, are re-ordered and assigned extended intelligence information. However, the invention is not so limited. Each basic block is single entry and single exit (SESE) with the exit through a branch instruction. Typically, the branch to another instruction is within a localized neighborhood such as within 400 instructions of the branch. The purpose of forming the execution sets (stage 140) is to determine the minimum number of basic blocks that can exist within an execution set such that the number of "instruction cache faults" are minimized. In other words, in a given execution set, branches or transfers out of an execution set are statistically minimized. TOLL in stage 140 can use a number of conventional techniques for solving this linear programming-like problem which is based upon branch distances and the like. The purpose is to define an execution set as set forth in FIG. 5 so that the execution set can be placed in a hardware cache, as will be discussed subsequently, in order to minimize instruction cache faults (i.e., transfers out of the execution set).

What has been set forth above is an example shown in Tables 1 through 6 of TOLL software 110 in a single context of use. In essence, TOLL determines the natural concurrencies within the instruction streams for each basic block within a given program. TOLL adds an instruction firing time (IFT) and a logical processor number (LPN) to each instruction in the determined natural concurrencies. Hence, all processing resources are statically allocated in advance of processing. The TOLL software of the present invention can be used in a number of different programs, each being used by the same or different users on a processing system of the present invention as will be explained next.

3. General Hardware Description

In FIG. 6, the block diagram format of the system architecture of the present invention termed "TDA" is shown. The TDA system architecture 600 includes a

5,021,945

23

memory sub-system 610 interconnected to a number of logical resource drivers (LRDs) 620 over a network 630. The logical resource drivers 620 are further interconnected to a group of context free processor elements 640 over a network 650. Finally, the group of processor elements 640 are connected to the shared resources containing a pool of register set and condition code set files 660 over a network 670. The LRD-memory network 630, the PE-LRD network 650, and the PE-context file network 670 are full access networks that could be composed of conventional crossbar networks, omega networks, banyon networks, or the like. The networks are full access (non-blocking in space) so that, for example, any processor element 640 can access any register file or condition code file in any context 660. Likewise, any processor element 640 can access any logical resource driver 620 and any logical resource driver 620 can access any portion of the memory subsystem 610. In addition, the PE-LRD and PE-context networks are non-blocking in time. In other words, these two networks guarantee access to any resource from any resource regardless of load conditions on the network. The architecture of the switching elements of the PE-LRD network 650 and the PE-context network 670 are considerably simplified since the TOLL software guarantees that collisions in the network will never occur. The diagram of FIG. 6 is a MIMD system wherein one context 660 corresponds to at least one user program.

The memory subsystem 610 can be constructed using a conventional memory architecture and conventional memory elements. There are many such architectures and elements that could be constructed by a person skilled in the art that would satisfy the requirements of this system. For example, a banked memory architecture could be used. *High Speed Memory Systems*, A.V. Pohm and O.P. Agrawal, Reston Publishing Co., 1983.

The logical resource drivers 620 are unique to the system architecture 600 of the present invention. Each LRD provides the data cache and instruction selection support for a single user (who is assigned a context) on a timeshared basis. The LRDs receive execution sets from the various users wherein one or more execution sets per context is stored on any given LRD. The instructions within the basic blocks of the stored execution sets are stored in queues based on the logical processor number. For example, if the system has 64 users and 8 LRDs, 8 users would share an individual LRD on a timeshared basis. The operating system determines who gets an individual LRD and for how long. The LRD is detailed at length subsequently.

The context free processor elements 640 are also unique to the TDA system architecture and will be discussed later. These processor elements display the context free stochastic property in which the future state of the system depends only on the present state of the system and not on the path by which the present state was achieved. As such, architecturally, the context free processor elements are uniquely different from conventional processor elements in two ways. First, the elements have no internal permanent storage or remnants of past events such as general purpose registers or program status words. Second, the elements do not perform any routing or synchronization functions. These tasks are performed by the software TOLL and are implemented in the LRDs. The significance of the architecture is that the context free processor elements of the present invention are a true shared resource to the LRDs.

24

Finally, the register set and condition code set files in contexts 660 can also be constructed of commonly available components such as AMD 29300 series register files, available from Advanced Micro Devices, 901 Thompson Place, P.O. Box 3453, Sunnyvale, California 94088. However, the particular configuration of the files 660 as shown in FIG. 6 is unique under the teachings of the present invention and will be discussed later.

The general operation of the present invention based upon the example set forth in Table 1 is illustrated with respect to the processor-context register file communication in FIGS. 7a, 7b, and 7c. As mentioned, the time-driven control of the present invention is found in the addition of the extended intelligence relating to the logical processor number (LPN) and the instruction firing time (IFT) as specifically set forth in FIG. 4. FIG. 7 generally represents the configuration of the context free processor elements PE0 through PE4 with registers R0 through R4, R10 and R11 of the register set and condition code set file 660.

In explaining the operation of the TDA system architecture 600 for the single user example in Table 1, reference is made to Tables 3 through 5. In the example, for instruction firing time T16, the context-PE network 670 is set up to interconnect processor element PE0 with registers R0 and R10, processor element PE1 is interconnected with registers R1 and R11 processor element PE2 is interconnected with register R4. Hence, during time T16, the three processor elements PE0, PE1, and PE2 process instructions I0, I1, and I4 concurrently and store the results in registers R0, R10, R1, R11, and R4. During time T16, the LRD 620 selects and delivers the instructions that can fire during time T17 to the appropriate processor elements. During instruction firing time T17, only processor element PE0 which is now assigned to process instruction I2 and it is interconnected with registers R0, R1, and R2. The BEU is also connected to the condition codes (not shown). Finally, during instruction firing time T18, only processor element PE0 is interconnected to registers R2 and R3.

Several important observations need to be made. First, when a particular processor element (PE) places the results in a given register, any processor element, during a subsequent instruction firing time (IFT), can be interconnected to that register when performing a subsequent operation. For example, processor element PE1 for instruction I1 loads register R1 with the contents of a memory location during IFT T16 as shown in FIG. 7a. During instruction firing time T17, processor element PE0 is now interconnected with register R1 to perform an additional operation on the results stored therein. Under the teachings of the present invention, each processor element (PE) is "totally coupled" to the necessary registers in the register file 660 during any particular instruction firing time (IFT) and, therefore, there is no need to move the data out of the register file for delivery to another resource; e.g. in another processor's register as in some conventional approaches.

In other words, under the teachings of the present invention, each process or element can be totally coupled, in any individual instruction firing time, to any one of the shared registers 660. In addition, under the teachings of the present invention, none of the processor elements has to contend (or wait) for the availability of a particular register or for results to be placed in a particular register as is found in some prior art systems. Also during any individual firing time, any processor element has full access to any configuration of registers

5,021,945

25
26

in the register set file 660 as if such registers were their own internal registers.

Hence, under the teachings of the present invention, the added intelligence as shown in FIG. 4, is based upon detected natural concurrencies within the object code. The detected concurrencies are analyzed by TOLL which logically assigns individual logical processor elements (LPNs) to process the instructions in parallel, and assigns unique firing times (IFTs) so that each processor element (PE) for its given instruction will have all necessary resources available for processing according to its instruction requirements. In the above example, the logical processor numbers correspond to the actual processor assignment or LPN0 to PE0, LPN1 to PE1, LPN2 to PE2, and LPN3 to PE3. The invention is not so limited since any order such as LPN0 to PE1, LPN1 to PE2, etc. could be used. Or, if the TDA system had only more or less than four processors, a different assignment could be used as will be discussed.

The timing control for the TDA system is provided by the instruction firing times—i.e., time-driven. As can be observed in FIGS. 7a through 7c, during each individual instruction firing time, the TDA system architecture composed of the processor elements 640 and the PE-register set file network 670, takes on a new and unique and particular configuration fully adapted for the individual processor elements to concurrently process instructions while making full use of all the available resources. The processor elements are context free since data, condition, or information relating to past processing is not required, nor does it exist internally to the processor element. The processor elements of the present invention react only to requirements of each individual instruction and are interconnected to the necessary shared registers.

4. Summary

In summary, the TOLL software 110 for each different program or compiler output 100 de-analyzes the natural concurrencies existing in each single entry, single exit (SESE) basic block (BB) and adds intelligence comprising a logical processor number (LPN) and an instruction firing time (IFT) to each instruction. In a MIMD system of the present invention as shown in FIG. 6, each context would contain a different user executing the same or different programs. Each user is assigned a different context and as shown in FIG. 7, the processor elements (PEs) are capable of individually accessing the necessary resources such as registers and condition codes storage required by the instruction. The instruction itself carries the shared resource information (i.e., registers and condition code storage). Hence, the TOLL software statically allocates only once for each program the necessary information for controlling the processing of the instruction in the TDA system architecture in FIG. 6 to insure a time-driven decentralized control wherein the memory, the logical resource drivers, the processor elements, and the context shared resources are totally coupled through their respective networks in a pure, non-blocking fashion. The logical resource drivers (LRDs) are receptive of the basic blocks formed in an execution set and are responsible for delivering the instructions to the processor element 640 on a per instruction firing time (IFT) basis. While the example shown in FIG. 7 is a simplistic representation for a single user, it is to be expressly understood that the delivery by the logical resource driver 620 of the instructions to the processor elements 640, in a multi-user sense, makes full use of the proces-

sor elements as will be fully discussed subsequently. Because the timing and the identity of the shared resources and the processor elements are all contained within the extended intelligence added to the instructions by the TOLL software, each processor element 640 is context free and, in fact, from instruction firing time to instruction firing time can process individual instructions of different users and their respective context. As will be explained, in order to do this, the logical resource driver 620, in a predetermined order, deliver the instructions to the processor element 640 through the PE-LRD network 650.

DETAILED DESCRIPTION

1. Detailed Description of Software

In FIGS. 8 through 11, the details of the TOLL software 110 of the present invention are set forth. In FIG. 8, the conventional output from a compiler is delivered to the TOLL software at the start stage 800. The following information is contained within the conventional compiler output 800: (a) instruction functionality, (b) resources required by the instruction, (c) locations of the resources (if possible), and (d) basic block boundaries. TOLL software then starts with the first instruction at stage 810 and proceeds to determine "which" resources are used in stage 820 and to determine "how" the resources are used in stage 830. This continues for each instruction within the instruction stream through stages 840 and 850 and was discussed in the previous section.

When the last instruction is processed in stage 840, a table is constructed and initialized with the "free time" and "load time" for each resource. Such a table is set forth in Table 7 for the inner loop matrix multiply example and at initialization contains all zeros. The initialization occurs in stage 860 and once constructed the TOLL software proceeds to start with the first basic block in stage 870.

TABLE 7

Resource	Load Time	Free Time
R0	T0	T0
R1	T0	T0
R2	T0	T0
R3	T0	T0
R4	T0	T0
R10	T0	T0
R11	T0	T0

In FIG. 9, the TOLL software continues the analysis of the instruction stream with the first instruction of the next basic block in stage 900. As stated previously, TOLL performs a static analysis of the instruction stream. Static analysis assumes (in effect) straight line code, i.e., each instruction is analyzed as it is seen in a sequential manner. In other words, static analysis assumes that a branch is never taken. For non-pipelined instruction execution, this is not a problem, as there will never by any dependencies that arise as a result of a branch. Pipelined execution is discussed subsequently (although, it can be stated that the use of pipelining will only affect the delay value of the branch instruction).

Clearly, the assumption that a branch is never taken is incorrect. However, the impact of encountering a branch in the instruction stream is straightforward. As stated previously, each instruction is characterized by the resources (or physical hardware elements) it uses. The assignment of the firing time (and hence, the logical

5,021,945

27

processor number) is dependent on how the instruction stream accesses these resources. Within TOLL, the usage of each resource is represented by data structures termed the free and load times for that resource. As each instruction is analyzed as it is seen, the analysis of a branch impacts these data structures in the following manner.

When all of the instructions of a basic block have been assigned firing times, the maximum firing time of the current basic block (the one the branch is a member of) is used to update all resources load and free times (to this value). When the next basic block analysis begins, the proposed firing time is then given as the last maximum value plus one. Hence, the load and free times for each of the register resources R0 through R4, R10 and R11 are set forth below in Table 8, for the example, assuming the basic block commences with a time of T16.

TABLE 8

Resource	Load Time	Free Time
R0	T15	T15
R1	I15	I15
R2	I15	I15
R3	I15	I15
R4	I15	I15
R10	I15	I15
R11	I15	T15

Hence, TOLL sets a proposed firing time (PFT) in stage 910 to the maximum firing time plus one of the previous basic blocks firing times. In the context of the above example, the previous basic blocks firing time is T15, and the proposed firing time for the instructions in this basic block commence with T16.

In stage 920, the first resource of the first instruction, which in this case is register R0 of instruction I0, is first analyzed. In stage 930 a determination is made as to whether or not the resource is read. In the above example, for instruction I0, register R0 is not read but written into and, therefore, stage 940 is next entered to make the determination of whether or not the resource is written. In this case, register R0 in instruction I0 is written into and stage 942 is entered. Stage 942 makes a determination as to whether the proposed firing time (PFT) for instruction I0 is less than or equal to the register resource free time for that resource. In this case, in Table 8, the resource free time for register R0 is T15 and, therefore, the instruction proposed firing time of T16 is greater than the resource free time of T15 and the determination is "no" and stage 950 is accessed.

The analysis by the TOLL software proceeds to the next resource which in the case for instruction I0 is register R10. This resource is both read and written by the instruction. Stage 930 is entered and a determination is made as to whether or not the instruction reads the resource. It does, so stage 932 is entered where a determination is made as to whether the current proposed firing time for the instruction (T16) is less than the resources load time (T15). It is not, so stage 940 is entered. Here a determination is made as to whether the instruction writes the resource - it does, so stage 942 is entered. In this stage a determination is made as to whether the proposed firing time for the instruction (T16) is less than the free time for the resource (T15). It is not, and stage 950 is accessed. The analysis by the TOLL software proceeds to the next resource which for instruction I0 is non-existent.

28

Hence, the answer to the determination of stage 950 is affirmative and the analysis then proceeds to FIG. 10. In FIG. 10, in stage 1000, the first resource for instruction I0 is register R0. The first determination in stage 1010 is whether or not the instruction reads the resource. As before, register R0 in instruction I0 is not read but written and the answer to this determination is "no" in which case the analysis then proceeds to stage 1020. In stage 1020, the answer to the determination as to whether or not the resource is written is "yes" and the analysis proceeds to stage 1022. Stage 1022 makes the determination as to whether or not the proposed firing time for the instruction is greater than the resource load time. In the example, the proposed firing time is T16 and with reference back to Table 8, the firing time T16 is greater than the load time T15 for register R0. Hence, the response to this determination is "yes" and stage 1024 is entered. In stage 1024, the resource load time is converted to the instructions proposed firing time and the table of resources updated to reflect that change. Likewise, stage 1026 is entered and the resource free time is updated to the instruction's proposed firing time plus one or T16 plus one equals T17.

Stage 1030 is then entered and a determination made as to whether there are any further resources used by this instruction. There are – register R10, and so analysis proceeds with this resource. Stage 1010 is entered where a determination is made as to whether or not the resource is read by the instruction. It is and so stage 1012 is entered where a determination is made as to whether the current proposed firing time (T16) is greater than the resources free time (T15). It is, so stage 1014 is entered where the resources free time is updated to reflect the use of this resource by this instruction. It is, and so stage 1022 is entered where a determination is made as to whether or not the current proposed firing time (T16) is greater than the load time of the resource (T15). It is, so stage 1024 is entered. In this stage, the resources load time is updated to reflect the firing time of the instruction, i.e., it is set to T16. Stage 1026 is then entered where the resource's free time is updated to reflect the execution of the instruction, i.e., it is set to T17. Stage 1030 is then entered where a determination is made as to whether or not this is the last resource used by the instruction. It is and stage 1040 is entered. The instruction firing time (IFT) is now set to equal the proposed firing time (PFT) of T16. Stage 1050 is then accessed which makes a determination as to whether or not this is the last instruction in the basic block which in this case is "no" and stage 1060 is entered to proceed to the next instruction, I1, which enters the analysis stage at A1 of FIG. 9.

In Table 9 below, that portion of the resource Table 8 is modified to reflect these changes. (Instructions I0 and I1 have been fully processed by TOLL.)

TABLE 9

Resource	Load Time	Free Time
R0	T16	T17
R1	I16	T17
R10	I16	T17
R11	I16	T17

The next instruction in the example is I1 and the identical analysis is had for instruction I1 for registers R1 and R11 as presented for instruction I0 with regis-

5,021,945

29   30

ters R0 and R10. Hence, Table 9, above, also shows the update of the resource table to reflect the analysis of instruction I1.

The next instruction in the basic block example is instruction I2 which involves a read of registers R0 and R1 and a write into register R2. Hence, in stage 910 of FIG. 9, the proposed firing time for the instruction is set to T16 (T15 plus 1). Stage 920 is then entered and the first resource in instruction I2 is register R0. The first determination made in stage 930 is "yes" and stage 932 is entered. At stage 932, a determination is made whether the instruction's proposed firing time of T16 is less than or equal to the resource register R0 load time of T16. It is important to note that the resource load time for register R0 was updated during the analysis of register R0 for instruction I0 from time T15 to time T16. The answer to this determination in stage 932 is that the proposed firing time equals the resource load time (T16 equals T16) and stage 934 is entered. In stage 934, the instruction proposed firing time is updated to equal the resource load time plus one or in this case T16 plus one equals T17. The instruction I2 proposed firing time is now updated to T17. Now stage 948 is entered and since instruction I2 does not write resource R0, the answer to the determination is "no" and stage 960 is entered to process the next resource which in this case is register R1.

Stage 960 causes the analysis to take place for register R1 and a determination is made in stage 930 whether or not the resource is read. The answer, of course, is "yes" and stage 932 is entered. This time the instruction proposed firing time is T17 and a determination is made whether or not the instruction proposed firing time of T17 is less than or equal to the resource load time for register R1 which is T16. Since the instruction proposed firing time is greater than the register load time (T17 is greater than T16), the answer to this determination is "no" and stage 940 is entered which does not result in any action and, therefore, the analysis proceeds to stage 950. The next resource to be processed for instruction I2 in stage 960 is resource register R2.

The first determination of stage 930 is whether or not this resource R2 is read. It is not and hence the analysis moves to stage 940 and then to stage 942. At this point in time the instruction I2 proposed firing time is T17 and in stage 942 a determination is made whether or not the instructions proposed firing time of T17 is less than or equal to resources, R2 free time which in Table 8 above is T15. The answer to this determination is "no" and therefore stage 950 is entered. This is the last resource processed for this instruction and the analysis continues in FIG. 10.

The analysis then proceeds to FIG. 10 and for instruction I2 the first resource R0 is analyzed. In stage 1010, the determination is made whether or not this resource is read and the answer is "yes." Stage 1012 is then entered to make the determination whether or not instruction I2 proposed firing time T17 is greater than the resource free time for register R0. In Table 9, the register free time for R0 is T17 and the answer to determination is "no" since both are equal. Stage 1020 is then entered which also results in a "no" answer transferring the analysis to stage 1030. Since this is not the last resource processed, stage 1070 is entered to advance the analysis to the next resource register R1. Precisely the same path through FIG. 10 occurs for register R1. Next, stage 1070 processes register R2. In this case, the answer to the determination of stage 1010 is "no" and

stage 1020 is accessed. Since register R3 for instruction I2 is written, stage 1022 is accessed. In this case, the instruction I2's proposed firing time is T17 and the resource load time is T15 from Table 8. Hence, the proposed firing time is greater than the load time and stage 1024 is accessed. Stages 1024 and 1026 cause the load time and the free time for register R2 to be advanced, respectively, to T17 and T18 and the resource table is updated as shown in FIG. 10:

TABLE 10

Resource	Load Time	Free Time
R0	T16	T17
R1	T16	T17
R2	T17	T18

As this is the last resource processed, the proposed firing time of T17 becomes the actual firing time in stage 1040 and the next instruction is analyzed.

It is in this fashion that each of the instructions in the inner loop matrix multiply example are analyzed so that when fully analyzed the resource table appears in Table 11 below:

TABLE 11

Resource	Load Time	Free Time
R0	T16	T17
R1	T16	T17
R2	T17	T18
R3	T18	T19
R4	T16	T17
R10	T16	T17
R11	T16	T17

In FIG. 11, the TOLL software after performing the tasks set forth in FIGS. 9 and 10 enter stage 1100. Stage 1100 sets all resource free and load times to the maximum of those within the given basic block. For example, the maximum time set forth in Table 11 is T18 and, therefore, all free and load times are set to time T18. Stage 1110 is then entered to make the determination whether or not this is the last basic block for processing. If not, stage 1120 is entered to proceed with the next basic block and, if so, stage 1130 is entered and starts with the first basic block in the instruction stream. The purpose of this analysis is to logically reorder the instructions within each basic block and to assign logical processor numbers. This is summarized in Table 6 for the inner loop matrix multiply example. Stage 1140 performs the function of sorting the instruction in each basic block in ascending order using the instruction firing time (IFT) as the basis. Stage 1150 is then entered wherein the logical processor numbers (LPNs) are assigned. In making the assignment of the processor elements, the instructions are assigned as a set to the same instruction firing time (IFT) on a first come, first serve basis. For example, in reference back to Table 6, the first set of instructions for firing time T16 are I0, I1, and I4 are assigned respectively to processors PE0, PE1, and PE2. Next, during time T17, the second set of instructions I2 and I5 are assigned to processors PE0 and PE1, respectively. Finally, during the final time T18, the final instruction I3 is assigned to processor PE0. It is to be expressly understood that the assignment of the processor elements could be done in other fashions and is based upon the actual architecture of the processor element. As is clear, in the preferred embodiment the set

5,021,945

31

of instructions are assigned to the logical processors on a first in time basis. After making the assignment, stage 1160 is entered to determine whether or not the last basic block has been processed and if not, stage 1170 brings forth the next basic block and the process is repeated until finished.

Hence, the output of the TOLL software results in the assignment of the instruction firing time (IFT) for each of the instructions as shown in FIG. 4. As previously discussed, the instructions are reordered based upon the natural concurrencies appearing in the instruction stream according to the instruction firing times and, then, individual logical processors are assigned as shown in Table 6. While the above discussion has concentrated on the inner loop matrix multiply example, the analysis set forth in FIGS. 9 through 11 can be made on any SESE basic block (BB) in order to detect the natural concurrencies contained therein and then to assign the instruction firing times (IFTs) and the logical processor numbers (LPNs) for each user's program. This intelligence is then added to the reordered instructions within the basic block. This is only done once for a given program and provides the necessary time-driven decentralized control and processor mapping information to run on the TDA system architecture of the present invention.

The purpose of execution sets, as shown in FIG. 12, is to optimize program execution by maximizing instruction cache hits within an execution set or, in other words, to statically minimize transfers by a basic block within an execution set to a basic block in another execution set. Support of execution sets consists of three major components: data structure definitions, pre-execution time software which prepares the execution set data structures, and hardware to support the fetching and manipulation of execution sets in the process of executing the program.

The execution set data structure consists of a set of one or more basic blocks and an attached header. The header contains the following information: the address 1200 of the start of the actual instructions (this is implicit if the header has a fixed length), the length of the execution set 1210 (or the address of the end of the execution set), and zero or more addresses 1220 of potential successor (in terms of program execution) execution sets.

The software to support execution sets manipulates the output of the post-compile processing which performs dependency analysis, resource analysis, resource assignment, and individual instruction stream re-ordering. The formation of execution sets uses one or of execution of basic blocks, and the grouping of basic blocks more algorithms for determining the probable order and frequency of execution of basic blocks, and the grouping of basic blocks accordingly. The possible algorithms are similar to the algorithms used in solving linear programming problems for least-cost routing. In the case of execution sets, cost is associated with branching. Branching between basic blocks contained in the same execution set incurs no penalty with respect to cache operations: it is assumed that the basic blocks of an execution set are resident in the cache in the steady state. Cost is associated with branching between basic blocks in different execution sets, because the target execution set's basic blocks may not be in cache. Cache misses delay program execution while the retrieval of the appropriate block from main memory to cache is made.

32

There are several possible algorithms which can be used to assess and assign costs under the teaching of the present invention. One algorithm is the static branch cost approach. Here one begins by placing basic blocks into execution sets based on block contiguity and the maximum allowable execution set size (this would be an implementation limit, such as maximum instruction cache size). The information about branching between basic blocks is known and is an output of the compiler. Using this information, one calculates the "cost" of the resulting grouping of basic blocks into execution sets, based on the number of (static) branches between basic blocks in different execution sets. One can then use standard linear programming techniques to minimize this cost function, thereby obtaining the "optimal" execution set cover. This algorithm has the advantage of ease of implementation; however, it ignores the actual dynamic branching patterns during actual program execution.

Other algorithms could be used under the teachings of the present invention which provide better estimation of acutal dynamic branch patterns. One example would be the collection of actual branch data from a program execution, and re-grouping of basic blocks using weighted assignment of branch costs based on the actual inter-block branching. Clearly, this approach is data dependent. Another approach would be to allow the programmer to specify branch probabilities, after which the weighted cost assignment would be made. This approach has the disadvantages of programmer intervention and programmer error. Still other approaches would be based using parameters, such as limiting the number of basic blocks per execution set, and applying heuristics to these parameters.

The algorithms described above are not unique to the problem of creating execution sets. However, the use of execution sets as a means of optimizing instruction cache performance is novel. Like the novelty of pre-execution time assignment of processor resources, the pre-execution time grouping of basic blocks for maximizing cache performance is not found in prior art.

The final element required to support execution sets is the hardware. As will be discussed subsequently, this hardware includes storage to contain the current execution set starting and ending addresses and to contain the other execution set header data. The existence of execution sets and the associated header data structures are, in fact, transparent to the actual instruction fetching from the cache to the processor elements. The latter depends strictly upon the individual instruction and branch addresses. The execution set hardware operates independently of instruction fetching to control the movement of instruction words from main memory to the instruction cache. This hardware is responsible for fetching basic blocks of instructions into the cache until either the entire execution set resides in cache or program execution has reached a point such that a branch has occurred to a basic block outside the execution set. At this point, if the target execution set is not resident in cache, the execution set hardware begins fetching the target execution set's basic blocks.

In FIG. 13, the structure of the register set file of context zero of the contexts 660 is set forth. As shown in FIG. 13, there are L levels of register sets with each register set containing N separate registers. For example, N could equal 31 for a total of 32 registers. Likewise, the L could equal 15 for a total of 16 levels. Note that these registers are not shared between levels; i.e.

5,021,945

33

each levels' set of registers is physically distinct from each other level.

Each level of registers corresponds to the registers available to a subroutine instantiation at a particular depth relative to the main program. In other words, level zero corresponds to the set of registers available to the main program, level one to any subroutine that is called directly from the main program. Level two corresponds to any subroutine called directly by a first level subroutine, level three to any subroutine called directly by a level two subroutine and so on.

As these sets of registers are independent, the number of levels corresponds to the number of subroutines that can be nested before having to physically share any registers between subroutines; i.e. before having to flush any registers to memory. The register sets in their different levels constitute a shared resource of the present invention and significantly saves system overhead in subroutine calls in that only rarely do sets of registers need to be pushed onto a stack in memory.

Communication between different levels of subroutines takes place in the preferred embodiment by allowing each routine three possible levels from which to obtain a register; the current level, the previous (calling) level and the global (main program) level. The designation of which level is to be accessed uses the static SCSM information attached to the instruction by the TOLL software. This can be illustrated by a subroutine call for a SINE function that takes as its argument a value representing an angular measure and returns the trigonometric SINE of that measure. This is set forth in Table 12:

TABLE 12

Main Program	Purpose
LOAD X, R1	Load X from memory into Reg R1 for parameter passing
CALL SINE	Subroutine Call - Returns result in Reg R2
LOAD R2, R3	Temporarily save results in Reg R3
LOAD Y, R1	Load Y from memory into Reg R1 for parameter passing
CALL SINE	Subroutine Call - Returns result in Reg R2
MULT R2, R3, R4	Multiply Sin (x) with Sin (y) and store result in Reg R4
STORE R4, Z	Store final result in memory at Z

The SINE subroutine is set forth in Table 13:

TABLE 13

Instruction	Subroutine	Purpose
I0	Load R1(10), R2	Load Reg R2, level 1 with contents of Reg R1, level 0
Ip-1	(Perform SINE), R7	Calculate SINE function and store result in Reg R7, level 1
Ip	Load R7, R2(10)	

34

Hence, under the teachings of the present invention and with reference to FIG. 14, instruction I0 of the subroutine loads register R1 of the current level (the subroutine's level or called level) with the contents of register R2 from the previous level (the calling routine or level). Note that the subroutine has a full set of registers with which to perform the processing independent of the calling routines register set. Upon completion of the subroutine call, instruction Ip causes register R7 of the current level to be stored into register R2 of the calling routines level (which returns the results of the SINE routine back to the calling program's register set).

The transfer between the levels occurs through the use of the SCSM statically provided information which contains the current procedural level of the instruction (i.e., the called routine or level), the previous procedural level (i.e. the calling routine or level) and the context identifier. The context identifier is only used when processing a number of programs in a multiuser system. This is shown in Table 13 for register R1 (of the calling routine) as R1(10) and for register R2 as R2(10). Note all registers of the current level have appended an implied (00) signifying current procedural level.

This differs substantially from prior art approaches where physical sharing of registers occurs between registers of a subroutine and its calling routine. The limiting of the number of registers that are available for use by the subroutine requires more system overhead for storing registers in memory. See, for example, the MIPS approach as set forth in "Reduced Instruction Set Computers" David A. Patterson, Communications of the ACM, January, 1985, Vol. 28, #1, Pgs. 8–21. In that reference, the first sixteen registers are local registers to be used by the subroutine, registers 16 through 23 are shared between the calling routine and the subroutine, and registers 24 through 31 are shared between the global (or main) program and the subroutine. Clearly, out of 32 registers that are accessible by the subroutine, only 16 can be privately used by the subroutine in the processing of its program. In the processing of complex subroutines, the remaining registers that are private to the subroutine may not (in general) be sufficient for the processing of the subroutine. Data shuffling (entailing the storing of intermediate data in memory) would occur resulting in significant overhead in the processing of the routine.

Under the teachings of the present invention, the transfers between the levels occur at compile time by adding the requisite information to the register identifiers as shown in FIG. 4, to appropriately map the instructions between the various levels. Hence, a completely independent set of registers are available to the calling routine and to each level of the subroutines. The calling routine, in addition to accessing its own complete set of registers, can also gain direct access to a higher set of registers using the aforesaid static SCSM mapping code added to the instruction as previously discussed. There is literally no reduction in the size of the register sets available to the subroutines as specifically found in prior art approaches. Furthermore, the mapping code for the SCSM information can be a field of sufficient length to access any number of desired levels. For example, a calling routine can access up to seven higher levels in addition to its own registers with a field of three bits. The present invention is not to be limited to any particular number of levels nor to any particular number of registers within a level. Under the

5,021,945

35

teachings of the present invention, the mapping shown in FIG. 14 is a logical mapping and not a conventional physical mapping. For example, if three levels such as calling routine level, the subordinate level, and the global level, three bit maps are used: calling routine (00), subordinate level (01), and global level (11). Thus, each user's program is analyzed and the static SCSM window code added prior to the issuance of the user to a specific LRD. When the user is assigned to a specific LRD, the LRD dependent and dynamic SCSM information is added as it is needed.

2. Detailed Description of the Hardware

As shown in FIG. 6, the TDA system 600 of the present invention is composed of memory 610, logical resource drivers (LRD) 620, context free processor elements (PEs) 640, and shared context storage 660. The following detailed description starts with the logical resource drivers since the TOLL output is loaded into this hardware.

a. Logical Resource Drivers (LRDs)

The details of an individual logical resource driver (LRD) are set forth in FIG. 15. As shown in FIG. 6, each logical resource driver 620 is interconnected to the LRD-memory network 630 on one side and to the processor elements 640 through the PELRD network 650 on the other side. If the present invention were a SIMD machine, then only one LRD is provided and only one context is provided. For MIMD capabilities one LRD and context is provided for each user so that in FIG. 6 up to "n" users are shown.

The logical resource driver 620 is composed of the data cache section 1500 and an instruction selection section 1510. In the instruction selection section, the following components are interconnected. The instruction cache address translation unit (ATU) 1512 is inter-connected to the LRD-memory network 630 over bus 1514. The instruction cache ATU 1512 is further interconnected over bus 1516 to an instruction cache control circuit 1518. The instruction cache control circuit 1518 is interconnected over lines 1520 to a series of cache partitions 1522a, 1522b, 1522c, and 1522d. Each of the cache partitions are respectively connected over busses 1524a 1524b, 1524c, and 1524d to the LRD-memory network 630. Each cache partition circuit is further interconnected over lines 1536a, 1536b, 1536c, and 1536d to a processor instruction queue (PIQ) bus interface unit 1544. The PIQ bus interface unit 1544 is connected over lines 1546 to a branch execution unit (BEU) 1548 which in turn is connected over lines 1550 to the PE-context network 670. The PIQ bus interface unit 1544 is further connected over lines 1552a, 1552b, 1552c, and 1552d to a processor instruction queue (PIQ) buffer unit 1560 which in turn is connected over lines 1562a, 1562b, 1562c, and 1562d to a processor instruction queue (PIQ) processor assignment circuit 1570. The PIQ processor assignment circuit 1570 is in turn connected over lines 1572a, 1572b, 1572c, and 1572d to the processor elements 640.

On the data cache portion 1500, the data cache ATU 1580 is interconnected over bus 1582 to the LRD-memory network 630 and is further interconnected over bus 1584 to the data cache control circuit 1586 and over lines 1588 to the data cache interconnection network 1590. The data cache control 1586 is also interconnected to data cache partition circuits 1592a, 1592b, 1592c and 1592d over lines 1593. The data cache partition circuits, in turn, are interconnected over lines 1594a, 1594b, 1594c, and 1594d to the LRD-memory

36

network 630. Furthermore, the data cache partition circuits 1592 are interconnected over lines 1596a, 1596b, 1596c, and 1596d to the data cache interconnection network 1590. Finally, the data cache interconnection network 1590 is interconnected over lines 1598a, 1598b, 1598c, and 1598d to the PE-LRD network 650 and hence to the processor elements 640.

The operation of each logical resource driver (LRD) 620 shown in FIG. 15 will now be explained. As stated previously, there are two sections to the LRD, the data cache portion 1500 and the instruction selection portion 1510. The data cache portion 1500 acts as a high speed data buffer between the processor elements 640 and memory 610. Note that due to the number of memory requests that must be satisfied per unit time, the data cache 1500 is interleaved. All data requests made to memory by the processor element 640 are issued on the data cache interconnection network 1590 and intercepted by the data caches 1592. The requests are routed to the appropriate data caches 1592 by the data cache interconnection network 1590 using the context identi-fier that is part of the dynamic SCSM information at-tached to each instruction by the LRD that is executed by the processors. The address of the desired datum determines which cache partition the datum resides in. If the requested datum is present (i e., a cache hit oc-curs), the datum is sent back to the requesting processor element 640.

If the requested datum is not present, the address delivered to the cache 1592 is sent to the data cache ATU 1580 to be translated into a system address and this address is then issued to memory. In response, a block of data from memory (a cache line or block) is delivered into the cache partition circuits 1592)Vunder control 1586. The requested data that is resident in this cache block is then sent through the data cache inter-connection network 1590 to the requesting processor element 640. It is to be expressly understood that this is only one possible design. The data cache portion is of conventional design and many possible implementations are realizable to one skilled in the art. As the data cache is of standard functionality and design, it will not be discussed further.

The instruction selection portion 1510 of the LRD consists of three major functions; instruction caching, instruction queueing and branch execution. The system function of the instruction cache portion 1510 is typical of any instruction caching mechanism. It acts as a high speed instruction buffer between the processors and memory. However, the current invention presents methods for realizing this function that are unique.

The purpose of the instruction cache 1510 is to re-ceive execution sets from memory, place the sets into the caches 1522 and furnish the instructions within the sets on an as needed basis to the processor elements 640. As the system contains multiple independent processors elements 640, requests to the instruction cache are for a set of concurrently executable instructions. Again, due to the number of requests that must be satisfied per unit time, the instruction cache is interleaved. The set size ranges from none to the number of processors available to the user. The sets are termed packets, although this does not necessarily imply that the instructions are stored in a contiguous manner. Instructions are fetched from the cache on the basis of their instruction firing time (IFT). The next instruction firing time register contains the firing time of the next packet of instruc-tions to be fetched. This register may be loaded by the

5,021,945

37

branch execution unit of the context as well as incremented by the cache control unit when an instruction fetch has been completed.

The next IFT register is a storage register that is accessible from the context control unit and the branch execution unit. Due to its simple functionality, it is not explicitly shown. Technically, it is a part of unit 1518, the instruction cache control unit, and is further buried in the control unit 1660. The key point here is that the NIFTR is merely a storage register and does not necessarily perform a sophisticated function.

The instruction cache portion 1510 receives an execution set from memory over bus 1524 and, in a round robin manner, places instructions word into each cache partition, 1522a, 1522b, 1522c and 1522d. In other words, each instructions in the execution set is delivered wherein the first instruction is delivered to cache partition 1522a, the second instruction to cache partition 1522b, the third instruction to cache partition 1522c and the fourth instruction to cache partition 1522d. The next instruction is then delivered to cache partition 1522a and so on until all of the instructions in the execution set are delivered into the cache partition circuits.

All the words delivered to the cache partitions are not necessarily stored in the cache. As will be discussed, the execution set header and trailer may not be stored. Each cache partition attaches a unique identifier (termed a tag) to all the information that is to be stored in that cache partition. This is used to verify that information obtained from the cache is indeed the information desired. When a packet of instructions is requested, each cache partition determines if the partition contains an instruction that is a member of the requested packet. If none of the partitions contain an instruction that is a member of the requested packet (i.e., a miss occurs), the execution set that contains the requested packet is requested from memory in a manner analogous to a data cache miss.

If a hit occurs (i.e., at least one of the partitions 1522 contain an instruction from the requested packet), the partition(s) attach any appropriate dynamic SCSM information to the instruction(s). The dynamic SCSM information which is attached to each instruction is important for multi-user applications. The dynamically attached SCSM information identifies the context, n, of FIG. 6 assigned to a given user. Hence, under the teachings of the present invention, the system 600 is capable of delay free switching among many user contexts without requiring a master processor or access to memory.

The instruction(s) are then delivered to the PIQ bus interface unit 1544 of the LRD 620 where it is routed to the appropriate PIQ buffers 1560 by the logical processor number (LPN) contained in the extended intelligence that the TOLL software attached to the instruction. The instructions in the PIQ buffer with 1560 are buffered up for assignment to the actual processor elements 640 which is performed by the PIQ processor assignment unit 1570. The assignment of the physical processor elements is performed on the basis of the number of processor elements currently available and the number of instructions that are available to be assigned. These numbers are dynamic. The selection process is set forth below.

The details of the instruction cache control 1560 of each cache partition 1522 of FIG. 15 are set forth in FIG. 16. In each cache partition circuit 1522, five circuits are utilized. The first circuit is the header route circuit 1600 which routes an individual word in the

38

header of the execution set over path 1520b to the instruction cache control unit 1660. The control of the header route circuit 1600 by the control unit 1660 is also over path 1520b through the header path select circuit 1602. The header path select circuit 1602 based upon the address received over lines 1502b from the control unit 1660 selectively activates the required number of header routers 1600 in the cache partitions. For example, if the execution set has two header words, only the first two header route circuits 1600 are activated by the header path select circuit 1602 which causes the header information to be delivered over bus 1520b to the control unit 1660 from the two activated header route circuits 1600. As mentioned, each word in the execution set is delivered to each successive cache partition circuit 1552.

Assume that the example of table 1 comprises an entire execution set and that appropriate header words appear at the beginning of the execution set. The instructions with the earliest instruction firing times (IFTs) listed first and with the lowest logical processor number first are:

TABLE 14

	Header Word 1	
---	Header Word 2	
I0	(T16)	(PE0)
I1	(T16)	(PE1)
I4	(T16)	(PE2)
I2	(T17)	(PE0)
I5	(T17)	(PE1)
I3	(T18)	(PE0)

Hence, the example of Table 1 (i.e., the matrix multiply inner loop, now has associated with it two header words and the extended information of the firing time (IFT) and the logical processor number (LPN). As shown in Table 14, the instructions were reordered by the TOLL software according to firing times. Hence, as the execution set shown in Table 14 is delivered through the LRD-memory network 630 from memory, the first word is routed by partition CACHE0 to the control unit 1660. The second word is routed by partition CACHE1 to the control unit 1660, instruction I0 is delivered into partition CACHE2, instruction I1 into partition CACHE3, instruction I2 into partition CACHE0, and so forth. As a result, the caches partition 1522 now contain the instructions as shown in Table 15:

TABLE 15

Cache0	Cache1	Cache2	Cache3
—	—	I0	I1
I4	I2	I3	I3

It is important to clarify, the above example has only one basic block in the execution set (i.e., a simplistic example). In actuality, an execution set would have a number of basic blocks.

The instructions are then delivered into a cache random access memory (RAM) 1610 resident in each cache for storage. Each instruction is delivered from the header router 1600 over a bus 602 into the tag attaching circuit 1604 and then over line 1606 into the RAM 1610. The tag attacher circuit 1604 is under control of a tag generation circuit 1612 and is interconnected therewith over line 1520c. Cache RAM 1610 could be a conven-

5,021,945

39

tional cache high speed RAM as found in conventional superminicomputers.

The tag generation circuit 1612 provides a unique identification code (ID) for attachment to each instruction before storage of that instruction in the designated RAM 1610. The assigning of process identification tags to instructions stored in cache circuits is conventional and is done to prevent aliasing of the instructions. "Cache Memories" by Alan J. Smith, ACM Computing Surveys, Vol. 14, September, 1982. The tag comprises a sufficient amount of information to uniquely identify it from each other instruction and user. The instructions already include the IFT and LPN, so that subsequently, when instructions are retrieved for execution, they can be fetched based on their firing times. As shown in Table 16, below, each instruction containing the extended information and the hardware tag is stored as shown for the above example:

TABLE 16

CACHE0:	I4(T16)(PE2)(ID2)
CACHE1:	I2(T17)(PE0)(ID3)
CACHE2:	I0(T16)(PE0)(ID0)
	I5(T17)(PE1)(ID4)
CACHE3:	I1(T16)(PE1)(ID1)
	I3(T18)(PE0)(ID5)

As stated previously, the purpose of the cache partition circuits 1552 is to provide a high speed buffer of the between the slow main memory 610 and the fast processor elements 640. Typically, the cache RAM 1610 is a high speed memory capable of being quickly accessed If the RAM 1610 were a true associative memory; as can be witnessed in Table 16, each RAM 1610 could be addressed based upon instruction firing times (IFTs). At the present, such associative memories are not economically justifiable and an IFT to cache address translation circuit 1620 must be utilized Such a circuit is conventional in design and controls the addressing of - each RAM 1610 over bus 1520d. The purpose of circuit 1620 is to generate the RAM address of the desired instructions given the instruction firing time. Hence, for instruction firing time T16, CACHE0, CACHE2, and CACHE3, as seen in Table 16, would produce instructions I4, I0, and I1 respectively. Hence, when the cache RAMs 1610 are addressed, those instructions associated with a specific firing time are delivered into a tag compare and privilege check circuit 1630.

The purpose of the tag compare and privilege check circuit 1630 is to compare the hardware tags (ID) to the generated tags to verify that the proper instruction has been delivered Again, the tag is generated through a generation circuit 1632 which is interconnected to the tag compare and privilege check circuit 1630 over line 1520e. A privilege check is also performed on the instruction delivered to verify that the operation requested by the instruction is permitted given the privilege status of the process (e g , system program, application program, etc.) This is a conventional check performed by computer processors which support multiple levels of processing states. The hit/miss circuit 1640 determines which RAMs 1610 have delivered the proper instructions to the PIQ bus interface unit 1544 in response to a specific instruction fetch request.

For example, and with reference back to Table 16, if the RAMs 1610 are addressed by circuit 1620 for instruction firing time T16, CACHE0, CACHE2, and CACHE3 would respond with instructions thereby

40

comprising a hit indication on those cache partitions. Cache 1 would not respond and that would constitute a miss indication and this would be determined by circuit 1640 over line 1520g. Likewise, for instruction firing time T16 three instructions are delivered Each addressed instruction is then delivered over bus 1632 into the SCSM attacher 1650 wherein any dynamic SCSM information is added onto each instruction by the hardware 1650.

When all of the instructions associated with an individual firing time have been read from the RAM 1610, the hit and miss circuit 1640 over lines 1646 informs the instruction cache control unit 1660 of this information. The instruction cache control unit 1660 contains the next instruction firing time register 1518 which increments the instruction firing time to the next value. Hence, in the example, upon the completion of reading all instructions associated with instruction firing time T16, the instruction cache control unit 1660 increments to the next firing time, T17 and delivers this information over lines 1664 to the access resolution circuit 1670, and over lines 1666 to the tag compare and privilege check circuit 1630. Also note that there may be firing times which have no valid instructions, possibly due to operational dependencies detected by TOLL. In this case, no instructions would be fetched from the cache and transmitted to the PIQ.

The present invention can be a multiuser computer architecture capable of supporting several users simultaneously in both time and space. In previous prior art approaches (CDC, IBM, etc.), multiuser support was accomplished by timesharing the processor(s). In other words, the processors were shared in time. In this system, multiuser support is accomplished by assigning an LRD to each user that is given time on the processor elements Thus, there is a spatial aspect to the sharing of the processor elements. The operating system of the machine would assign users to the LRDs in a time-shared manner, thereby adding the temporal dimension to the sharing of the processors.

Hence, multiuser support is accomplished by the multiple LRDs, the use of context free processor elements, and the multiple context support present in the register and condition code files As several users may be executing in the processor elements at a time, additional pieces of information must be attached to each instruction prior to its execution in order to uniquely identify the instruction source and any resources that it may use. For example, a register identifier must contain the procedural level and context identifier as well as the actual register number Memory addresses must also contain the LRD identifier that the instruction was issued from in order to get routed through the data cache interconnection network to the appropriate data cache.

The information comprises two components - static and dynamic and, as maintained, is termed shared context storage mapping (SCSM). The static information is composed of information that the compiler or TOLL can glean from the instruction stream. For example, the register window tag would be generated statically and attached to the instruction prior to its being received by an LRD.

The dynamic information is hardware attached to the instruction by the LRD prior to its issuance to the processors. This information is composed of the context/LRD identifier that is issuing the instruction, the current procedural level of the instruction, the process

5,021,945

41

identifier of the current instruction stream, and the instruction status information that would normally be contained in the processors of a system with processors that are not context free. This later information would be composed of error masks, floating point format modes, rounding modes and so on.

The operation of the circuitry in FIG. 16 can be summarized as follows. One or more execution sets are delivered into the instruction cache circuitry of FIG. 16, the header information for each set is delivered to one or more successive cache partitions and is routed into the control unit 1660. The remaining instructions in the execution set are then individually, on a round robin basis, routed into each successive cache partition unit 1552, a hardware identification tag is attached to each instruction and it is stored in RAM 1610. As previously discussed, each execution set is of sufficient length to minimize instruction cache defaults and the RAM 1610 is of sufficient size to store the execution sets. When the processor elements require the information, the instructions stored in the RAMs 1610 are read out, the identification tags are verified and the privilege status checked. The number and cache locations of valid instructions matching the appropriate IFTs are determined. The instructions are then delivered to PIQ bus interface unit 1544. The information that is delivered to the PIQ bus interface unit 1544 is set forth in Table 17 including the identification tag (ID) and the hardware added SCSM information.

TABLE 17

CACHE0:	I4(T16)(PE2)(ID2)(SCSM0)
CACHE1:	I2(T17)(PE0)(ID3)(SCSM1)
CACHE2:	I0(T16)(PE0)(ID0)(SCSM2)
	I5(T17)(PE1)(ID4)(SCSM3)
CACHE3:	I1(T16)(PE1)(ID1)(SCSM4)
	I3(T18)(PE0)(ID5)(SCSM5)

In FIG. 17, the details of the PIQ bus interface unit 1544 and the PIQ buffer unit 1560 are set forth. These circuits function as follows. The PIQ bus interface unit 1544 receives instructions as set forth in Table 17, above, over leads 1536. These instructions access, in parallel, a series of bus interface units (BIUs) 1700. The bus interface units 1700 are interconnected together in a full access non-blocking network by means of connections 1710 and 1720 over lines 1552 to the PIQ buffer unit 1560. Each bus interface unit (BIU) 1700 is a conventional address comparison circuit composed of: TI 74L85 4 bit magnitude comparators, Texas Instruments Company, P.0. Box 225012, Dallas, Texas 75265. In the matrix multiply example, for instruction firing time T16, CACHE0 contains instruction I4 and CACHE3 (corresponding to CACHE N in FIG. 17) contains instruction I1. The logical processor number assigned to instruction I4 is PE2 and, therefore, the logical processor number PE2 activates a select (SEL) signal of the bus interface unit 1700 for processor instruction queue 2 (BIU3). In this example, only BIU3 is activated and the remaining bus interface units 1700 are not activated. Likewise, for CACHE3 (CACHE N), BIU2 is activated for processor instruction QUEUE 1.

The PIQ buffer unit 1560 is comprised of a number of processor instruction queues 1730 which store the instructions received from the PIQ bus interface unit 1544 in a first in-first out (FIFO) fashion as shown in Table 18:

42

TABLE 18

PIQ0	PIQ1	PIQ2	PIQ3
I0	I1	I4	--
I2	--	--	--
I3	--	--	--

In addition to performing instruction queueing functions, the PIQs 1730 also keep track of the execution status of each instruction that are issued to the processor elements 640. In an ideal system, instructions could be issued to the processor elements every clock cycle without worrying about whether or not the instructions have finished execution. However, the processor elements 640 in the system may not be able to complete an instruction every clock cycle due to exceptional conditions occurring, such as a data cache miss and so on. As a result, each PIQ 1730 tracks all instructions that it has issued to the processor elements 640 that are still in execution. The primary result of this tracking is that the PIQ's 1730 perform the instruction clocking function for the LRD 620. In other words, the PIQs 1730 determine when the next firing time register can be updated when executing straightline code. This in turn begins a new instruction fetch cycle.

Instruction clocking is accomplished by having each PIQ 1730 form an instruction done signal that specifies that the instruction(s) issued by a given PIQ have executed or proceeded to the next stage in the case of pipelined PEs. This is then combined with all other PIQs instruction done signals from this LRD and used to gate the increment signal that increments the next firing time register. These signals are delivered over lines 1564 to the instruction cache control 1518.

The details of the PIQ processor assignment circuit 1570 is set forth in FIG. 18. The PIQ processor assignment circuit 1570 contains a set of network interface units (NIUs) 1800 interconnected in a full access switch to the PE-LRD network 650 and then to the various processor elements 640. Each network interface unit (NIU) 1800 is comprised of the same circuitry as the bus interface units (BIU) 1700 of FIG. 17. In normal operation, the processor instruction queue (PIQ0) directly accesses processor element 0 and NIU0 is activated and the remaining network interface units NIU1, NIU2, NIU3, for PIQ are deactivated. Likewise, processor instruction PIQ3 normally accesses processor element 3 having its NIU3 activated and the corresponding NIU0, NIU1, deactivated. The activation of which network interface unit 1800 is under the control of an instruction select and assignment unit 1810.

This unit 1810, receives signals from the PIQs within the LRD over lines 1811 that the unit 1810 is a member of, and from all other LRDs unit 1810 over lines 1813, and from the processor elements 640 through the network 650. Each PIQ furnishes the unit a signal that corresponds to "I have an instruction that is ready to be assigned to a processor." The other units furnish this unit and every other unit a signal that corresponds to "My PIQ #x has an instruction ready to be assigned to a processor." Finally, the processor elements furnish the unit and all other units in the system a signal that corresponds to "I can accept a new instruction."

The unit 1810 transmits signals to the PIQs of the LRD over lines 1811, the network interface units 1800 of the LRD and the other units 1810 of the other LRDs in the system over lines 1813. The unit transmits a signal
